22 **Abstract**

23

24 The objective of this study is to provide an approach for assessing the short-term  
25 risk of mountain pine beetle *Dendroctonus ponderosae* Hopkins (Coleoptera: Scolytidae)  
26 attack over large forested areas based on the spatial-temporal behavior of beetle spread.  
27 This is accomplished by integrating GIS, aerial overview surveys, and local indicators of  
28 spatial association (LISA) in order to measure the spatial relationships of mountain pine  
29 beetle impacts from one year to the next. Specifically, we implement a LISA method  
30 called the bivariate local Moran's  $I_i$  to estimate the risk of mountain pine beetle attack  
31 across the pine distribution of British Columbia, Canada. The bivariate local Moran's  $I_i$   
32 provides a means for classifying locations into separate qualitative risk categories that  
33 describe insect population dynamics from one year to the next, revealing where mountain  
34 pine beetle populations are most likely to increase, stay constant, or decline. The  
35 accuracy of the model's prediction of qualitative risk was higher in initial years and lower  
36 in later years of the study, ranging from 91% in 2002 to 72% in 2006. The risk rating can  
37 be continually updated by utilizing annual overview surveys, thus ensuring that risk  
38 prediction remains relatively high in the short-term. Such information can equip forest  
39 managers with the ability to allocate mitigation resources for responding to insect  
40 epidemics over very large areas.

43 mountain pine beetle, insect outbreaks.

44

45 **1. Introduction**

46 The mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Coleoptera:  
47 Scolytidae) is the most destructive insect pest of pine forests in western North America  
48 (Safranyik 1988). Since 1999, the insect has affected more than 16 million ha of pine  
49 forests in western Canada (Westfall and Ebata 2010). The current epidemic, largely  
50 located in British Columbia, has resulted in substantial commercial timber loss (Pederson  
51 2004), increase risk to fire and habitat loss (Jenkins et al. 2008, Coops et al. 2009), and  
52 alterations to carbon cycling processes (Coops and Wulder 2010; Kurz et al. 2008; Pfeifer  
53 et al. 2011). In addition, there is concern that the beetle will infest further beyond its  
54 historical range (Sambaraju et al., 2011) as warmer seasonal temperatures exacerbate the  
55 outbreak and permit it to move to higher latitudes and elevations than previously  
56 recorded (Logan et al. 2003), and across the geoclimate divide as defined by the Rocky  
57 Mountain range of North America (Safranyik et al. 2010). Such concerns indicate a need  
58 for risk analyses that can inform forest management decision making over vast areas in a  
59 timely manner.

60

61 In British Columbia, the mountain pine beetle mostly attacks lodgepole pine  
(*pinus contorta*) (Flint et al. 2009). The process begins in the summer as beetles emerge  
62 from their host and spend time in flight searching for a new tree to attack. Once located,  
63 the beetle attempts to bore through the bark and release pheromone chemicals to attract  
64 additional beetles to the suitable host (Powell et al. 2000). After boring through the  
65 phloem of the tree, beetles copulate and proceed to dig galleries that are used to oviposit  
66 (Raffa et al. 2008). As beetles bore through the bark, they inoculate the tree with two  
67 types of blue stain fungi that rapidly penetrate living tree cells, thereby impacting the

68 capacity for translocation of moisture and nutrients through the tree, consequentially  
69 limiting the ability of the tree ward off attack (Paine et al. 1997; Six and Paine 1998). The  
70 combination of pheromone release and fungi inoculation facilitates a mass attack of  
71 beetles on an individual tree that are needed to overcome a tree's defensive mechanisms  
72 (Safranyik 2004). Reproduction ensues in the weeks following tree mortality, and young  
73 beetles then overwinter under the bark and then emerge in the following summer to  
74 repeat the same process.

75 Individual trees vary in their susceptibility to attack as beetles have preference for  
76 trees that provide ample resources for reproduction and growth while also providing  
77 minimal resistance to attack (Berryman 1978). Trees with larger diameters, for example,  
78 receive relatively higher densities of attack because the rougher bark associated with  
79 larger trees is preferred for initiating galleries (Safranyik 1971), and the thicker phloem  
80 provides protection from predators and extreme temperatures (Reid 1963), thus  
81 increasing the likelihood of progeny survival. Beetles also prefer older trees, generally  
82 over 80 years of age, because their vigor diminishes as age increases (Safranyik 2004). In  
83 addition, dense stands of older trees are preferred as increased competition for resources  
84 comprise their ability to resist attack (Mitchell et al. 1983).

85 Identifying forest stands at risk to mountain pine beetle attack aids in the  
86 mitigation and prevention of outbreaks. The term risk in the bark beetle literature has  
87 come to refer to "the short-term expectancy of tree mortality in a stand as a result of  
88 mountain pine beetle infestation" (Shore et al., 2000, p.44), with risk being a function of  
89 both stand susceptibility (i.e., the ability of a stand to support a beetle population) and the  
90 magnitude of surrounding mountain pine beetle populations – often referred to as  
91 population pressure (Bentz et al. 1993).

92 When beetle infestations expand over large areas as has occurred with the current  
93 outbreak, estimating risk becomes a complicated task because of the data required for  
94 calculating susceptibility. Risk models with a susceptibility component (Amman et al.  
95 1978; Berryman 1978; Mahoney 1978; Schenk et al. 1980, Shore and Safranyik 1992)  
96 rely upon data that provide details concerning, for example, average tree age, tree  
97 diameter, phloem thickness, basal area, crown competition and stand growth. Such data  
98 can be collected and analyzed in a timely manner when infestations remain relatively  
99 small. However, large outbreaks require that risk models be applied over large areas,  
100 which means that models must then rely upon regional inventory records to provide the  
101 necessary data (Robertson et al. 2008). For example the British Columbia Ministry of  
102 Forests, Lands and Natural Resource Operations provides the Vegetation Resources  
103 Inventory (VRI), which is a photo-based, two-phased vegetation inventory with attributes  
104 estimates through a combination of aerial photo interpretation and ground sampling  
105 (BCMSRM 2002). The utility of such inventories becomes increasingly limited when  
106 bark beetle outbreaks cause changes to forest composition (via beetle-induced tree  
107 mortality or harvesting-based mitigation efforts) occur far more swiftly than inventory  
108 updates. This is especially true in British Columbia where the current mountain pine  
109 beetle outbreak has grown swiftly since 2000 (see Figure 1).

110

111 *Insert Figure 1 here*

112

113 In contrast to the data needs associated with estimating susceptibility under large-  
114 area mountain pine beetle outbreak scenarios, estimating population pressure under  
115 similar scenarios can be accomplished through the use of a single dataset: forest health  
116 aerial overview survey (AOS) data. In British Columbia, AOS are annual, systematic  
117 surveys of a broad range of forest health issues. Designed to cover the largest possible  
118 area, the AOS are conducted by trained practitioners in fixed-wing aircraft, who provide  
119 estimates of beetle-induced tree mortality (and other forest health information) (Wulder et  
120 al., 2006). The AOS is a strategic-level data source that is rapidly disseminated to the  
121 public (i.e., within 3 months of survey completion) (Wulder et al., 2009), and that can  
122 serve as a surrogate for beetle population pressure. Furthermore, because the AOS are  
123 conducted annually, changes in population pressure can be estimated across a region,  
124 which is important for determining if populations are increasing or decreasing in specific  
125 areas in order to prioritize mitigation efforts.

126 While focusing risk estimates solely on population pressure is only part of the risk  
127 equation, we posit that data on regional population dynamics collected from AOS can aid  
128 in identifying and prioritizing areas of imminent risk to mountain pine beetle infestations  
129 over large areas. As such, this study proposes a GIS-based risk rating system of mountain  
130 pine beetle infestations by integrating multi-year AOS data and local indicators of spatial  
131 association (LISA) (Anselin 1995) for estimating infestation risk at a regional scale. We  
132 extend previous applications of LISA for estimating mountain pine beetle infestations  
133 (Nelson and Boots 2008) by applying the bivariate local Moran's  $I_i$  to determine local  
134 spatial relationships in beetle infestations in subsequent years. The objective of  
135 developing a regional risk rating system based on surrogate measures of population  
136 pressure across multiple years is to inform management of where lies increasing, constant  
137 or declining risk. As mountain pine beetle population dynamics are controlled by  
138 numerous local and regional processes that interact with each other over time, it is  
139 difficult to project where populations will arrive, increase or diminish from one year to  
140 the next over a region without examining the spatial and temporal distributions of  
141 populations. We anticipate that this regional risk rating system will be able to be used in  
142 unison with more localized data on susceptibility characteristics in order to provide a  
143 more effective means of mitigating outbreaks.

144

## 145 **2. Methods**

### 146 **2.1 Study Site and Data**

147 The study site (see Figure 2) is defined by the distribution of lodgepole pine in  
148 British Columbia, which is an area covering approximately 30 million hectares of the  
149 provinces' 95 million hectare land mass (BC Ministry of Forests 2004). The pine  
150 distribution data exists as a 1km resolution raster grid in which each cell is represented by  
151 the estimated percentage of pine at that location. The dataset was developed by Robertson  
152 et al. (2009) to support estimates of the compositional change of pine forests in British  
153 Columbia due to mountain beetle attack.

154

155 *Insert Figure 2 here*

156

157 The severity of mountain pine beetle attack, which refers to the percentage of  
158 trees successfully attacked within a given area (Wulder et al., 2006), was used as a proxy

159 for beetle population levels. Severity information was acquired from annual forest health  
 160 aerial overview surveys (AOS)  
 161 (<http://www.for.gov.bc.ca/hfp/health/overview/overview.htm>), which are conducted  
 162 province-wide by trained observers in fixed-wing aircraft. These AOS are completed  
 163 quickly and efficiently, making them ideally suited for mapping the general location,  
 164 gross area, and general trend (i.e., increasing, decreasing, or stable) in damage caused by  
 165 mountain pine beetle over large areas. Damage is observed and recorded on basemaps  
 166 with scales of either 1:100,000 or 1:125,000, and a severity class (i.e., trace, light,  
 167 moderate, severe, or very severe) is assigned according to the proportion of pine trees that  
 168 are killed by the beetle (Table 1). The limitations of these survey data include large errors  
 169 of omission when damage is very light and a lack of rigorous positional accuracy. The  
 170 surveys were analyzed by Wulder et al. (2009) in order to develop spatial datasets  
 171 representing severity values across the province at the 1 ha scale. For this study, the data  
 172 were aggregated to a 1 km scale in order to agree with the resolution of the pine  
 173 distribution data.

174

## 175 2.2 Predicting Risk Classes

176 LISA represents a set of localized statistical approaches that typically measure the  
 177 relationship between individual locations and their surrounding neighbors to uncover  
 178 patterns of spatial clustering. For this study, we employ the local Moran's  $I_i$ , a  
 179 decomposition of the global Moran's  $I_i$ , for quantifying spatial autocorrelation. While the  
 180 global statistic provides an overall measure of spatial autocorrelation, the local Moran's  $I_i$   
 181 relates each observation to its neighbors and assigns them to classes with a value  
 182 indicating the degree of spatial autocorrelation. The local Moran's  $I_i$  estimates the  
 183 similarity in  $x$  between observation  $i$  and observations  $j$  in the neighborhood of  $i$  defined  
 184 by a matrix of weights  $w_{ij}$ . The strength of the relationship between the neighbors is  
 185 accordingly captured. The statistic, provided by Anselin (1995), is calculated as:

$$186 \quad I_i = \left[ \frac{\frac{z_i}{\left( \frac{\sum_i z_i^2}{i} \right)}}{\frac{n}{n}} \right] \sum_j w_{ij} z_j \quad (1)$$

187 where  $z_i = x_i - \bar{x}$ .

188 In essence, equation 1 standardizes value  $x$  for observation  $i$  to determine if it is  
 189 high or low relative to the mean, and standardizes values of  $x$  for  $j$  to determine if the  
 190 neighborhood is high or low relative to the mean. The standardization operates in a  
 191 similar manner as a statistical z-score that compares observations to the mean in order to  
 192 determine the observations' relative position within a distribution. In the absence of such  
 193 standardization, the resulting Moran's  $I_i$  values would be disproportionately influenced  
 194 by extreme values of severity. Multiplying the standardized value  $x$  for observation  $i$  and  
 195 the neighborhood  $j$  produces a scalar Moran's  $I_i$  value; these values can conceptually be  
 196 placed into one of four categories representing the relationship between each point and its  
 197 neighbors: (1) Low-Low, (2) High-Low, (3) Low-High, and (4) High-High. The results  
 198 from the local Moran's  $I_i$  operation can be visualized in a Moran's scatterplot that

199 displays the location of each observation within the solution space of its assigned class.  
 200 Within the scatterplot, the local Moran's  $I_i$  value describes the relative location of  
 201 observation  $i$  within the two-dimensional solution space of each category. Note that not  
 202 all Moran's  $I_i$  values are significant: a test of significance is computed for each point to  
 203 determine if the spatial relationship is significant given a specified level of confidence.  
 204 Thus, just because a Moran's  $I_i$  value provides a means for classifying a data point's  
 205 spatial relationship with its neighbors, it does not guarantee that this relationship is  
 206 significant. For further reading on the parameterization and utility of both the global and  
 207 local Moran's  $I_i$ , please see Tiefelsdorf and Boots (1995), Waldhor (1996), and Zhang et  
 208 al (2008).

209 An extension of this method is the bivariate local Moran's  $I_i$  in which variable  $x$   
 210 of observation  $i$  is compared to variable  $y$  of the neighborhood  $j$ . The modified equation  
 211 from for bivariate local Moran's  $I_i$  takes the form:

$$212 \quad I_i = \left[ \frac{z_i}{\left( \frac{\sum_i z_i^2}{i} \right)} \right] \sum_j w_{ij} (y_j - \bar{y}) \quad (2)$$

213  
 214 The bivariate Moran's  $I_i$  facilitates the examination of multi-temporal data  
 215 relating to mountain pine beetle severity. The severity at a location from two years prior  
 216 to the present (year  $t-2$ ) can be compared to the severity in its neighborhood at year  $t-1$   
 217 to determine the spatial and temporal patterns of beetle spread at time  $t$ . Examining the  
 218 relationship between tree mortality at a location in a specific year versus tree mortality in  
 219 the neighborhood in a subsequent year results in a severity rating that incorporates  
 220 change; in the absence of the temporal component of our analysis we would be ignoring  
 221 the potential that mountain pine beetle populations are increasing or decreasing in an  
 222 area. For example, severity in 2000 at a specific location is compared to severity in its  
 223 neighborhood in 2001. The resulting estimated bivariate local Moran's  $I_i$  class, (referred  
 224 to hereafter as risk class) is then used to represent risk for that location in 2002. This is  
 225 repeated for each year in order to retrieve the risk classes for the period between 2002  
 226 and 2006. Equation 2 thus becomes

$$227 \quad I_{i,t} = \left[ \frac{z_{i,t-2}}{\left( \frac{\sum_i z_{i,t-2}^2}{i} \right)} \right] \sum_j w_{ij} z_{j,t-1} \quad (3)$$

228 where  $I_{i,t}$  is the Moran's  $I_i$  for location  $i$  at time  $t$ ,  $z_{j,t-1} = x_{j,t-1} - \bar{x}_{j,t-1}$ , and

229  $z_{i,t-2} = x_{i,t-2} - \bar{x}_{i,t-2}$ .

230 The Moran's  $I_i$  identifies spatial autocorrelation in values extreme relative to  
231 mean values and subsequently facilitates the classification of locations into risk classes.  
232 A Moran's  $I_i$  scatterplot provides a depiction of how each observation can be categorized  
233 based on its relationship with its neighbors. The scatterplot's x-axis defines the value of  
234 observation  $i$  relative to the mean of all observations, while the y-axis defines the value of  
235 observations in the neighborhood of  $i$  relative to the mean of all observations. The  
236 scatterplot consists of four quadrants, each defining the relationship between an  
237 observation and its neighbors. Figure 3 depicts a Moran's  $I_i$  scatterplot in the context of  
238 this study. Class 1 (Low-Low) represents an observation  $i$  that experiences zero to  
239 minimal severity at time  $t-2$  and whose neighborhood experiences zero to minimal  
240 severity at time  $t-1$ . Therefore, we expect that observations in class 1 will not experience  
241 a significant increase in severity and hence have zero to minimal severity at time  $t$ . We  
242 term this the Null class as we do not expect large magnitude infestations in the immediate  
243 future. Locations in the Null class exhibit positive Moran's  $I_i$  values (the larger value the  
244 greater the difference in severity between the location and the mean neighborhood  
245 severity) in concert with low severity.

246  
247 *Insert Figure 3 here*

248  
249 Observations in class 2 (High-Low) experienced greater than average severity at  
250 time  $t-2$  and below average severity in the neighborhood at time  $t-1$ . These locations  
251 exhibit negative Moran's  $I_i$  values as the relationship between a location and its  
252 neighborhood are governed by negative spatial autocorrelation. Thus, we expect that the  
253 severity at  $t$  should be declining towards low to moderate severity because there exists a  
254 diminished attack severity in the neighborhood of  $i$  in the subsequent year. This class is  
255 referred to as the Decline class as it represents areas where infestations are expected to  
256 diminish.

257 Observations in class 3 (Low-High) are also defined by a negative spatial  
258 autocorrelation relationship as the locations experienced low severity at  $t-2$  but above  
259 average severity in the neighborhood at  $t-1$ . Therefore, severity should be increasing  
260 highest amongst all classes towards moderate to high severity because there exists greater  
261 insect population pressure in the neighborhood in the subsequent year. We refer to this  
262 class as the Increase class because such locations are experiencing a growth in the  
263 infestation.

264 Observations in class 4 (High-High) experienced higher than average severity at  $t-$   
265 2 and higher than average severity in the neighborhood at  $t-1$ ; this class, which exhibits  
266 positive Moran's  $I_i$  values, is thus defined as the Constant class. Our expectation for  
267 severity in class 4 depends on length of time a location has been in the class. For  
268 locations that enter class 4, we expect that severity will increase as heightened population  
269 levels attack stands of varying susceptibility. For locations in class 4 for multiple years,  
270 we expect severity to decline due to the diminishing availability of susceptible hosts.

271 The neighborhood in the local Moran's  $I_i$  should be representative of the distance  
272 over which a location exhibits a relationship with its surrounding area. With regards to  
273 mountain pine beetle dispersal, this task entails defining a neighborhood based on the  
274 distance that the insect typically fly during their summer dispersal period. We estimated a  
275 measure of insect dispersal by examining the nearest neighbor distance between cells that

276 exhibited attack in a specific year and cells that exhibited attack for the first time in the  
277 subsequent year. This measure represents our best estimate at determining the least  
278 distance that mountain pine beetle disperses from one year to the next. The bivariate local  
279 Moran's  $I_i$  was computed using the software program GeoDa (Anselin et al. 2006) – a  
280 GIS-based application focused on estimating local and global spatial relationships in  
281 attributes represented in GIS data.

282

### 283 **2.3 Risk Rating Evaluation**

284 The use of the bivariate local Moran's  $I_i$  to assign a risk class was first assessed  
285 by performing a cell-by-cell comparison between our estimated risk classes against  
286 observed severity classes in ArcGIS 10 (Esri 2011). The severity classes were defined  
287 using the Government of British Columbia's severity rating system shown in Table 1,  
288 which also include the total area in the province within each class in 2006. The Moran's  $I_i$   
289 is considered to be correct if:

- 290 1. *A cell assigned to the Null risk class at time  $t$  represents a location that*  
291 *belongs to the None severity class at time  $t$ .*
- 292 2. *A cell assigned to the Increase risk class represents a location that*  
293 *experienced an increase from one severity class to another (e.g. from light*  
294 *to moderate).*
- 295 3. *A cell assigned to the Constant risk class represents a location that (a) did*  
296 *not experience a change in severity classes and (b) is not in the None*  
297 *severity class.*
- 298 4. *A cell assigned to the Decline risk class represents a location that*  
299 *experienced a decline from one severity class to another (e.g. from moderate*  
300 *to light).*

301

302 The relationship between estimated and observed severity was also examined in a  
303 graphical context to determine if and how the Moran's  $I_i$  either over- or underestimated  
304 severity.

305 Next, we examined the distribution of risk classes with regards to our  
306 expectations (described in section 2.2) of how the classes should represent spread. During  
307 early years of the infestation, the Constant class should constitute the nucleus of the  
308 infestation, the Increase class will exist in the frontier of the infestation, and the Null  
309 class will compose the remainder of the landscape where beetle-induced tree mortality is  
310 absent. As the infestation increases over time, the cluster pattern remains the same with  
311 the exception of the Decline class emerging in the center of the infestation. The Decline  
312 class represents locations where host trees become exhausted and mountain pine beetle  
313 populations move onto alternative locations.

314

## 315 **3. Results**

### 316 **3.1 Estimating Neighborhood Size**

317 The appropriate neighborhood size for the local Moran's  $I_i$  statistic was estimated  
318 from the nearest neighbor calculations performed in ArcGIS 10 (Esri 2011) between the  
319 datasets representing successive years of attack. The results from the nearest neighbor  
320 analysis are presented in Figure 4. The frequency distributions represent the minimal  
321 distance over which mountain pine beetle dispersed in order to attack trees located in a

322 cell that had yet to experience attack. The majority of dispersal occurs within a distance  
323 of 3 km, while longer-range dispersal is observed at varying distances from one year to  
324 the next. We thus selected 3 km as our neighborhood size for the local Moran's  $I_i$   
325 statistic, which is supported by previous research (Safranyik 1989, Shore and Safranyik  
326 1992).

327

328 *Insert Figure 4 here*

329

### 330 **3.2 Assessment of Risk Classes**

331 The results from the accuracy test from each year of the study are presented in  
332 Figure 5. The local Moran's  $I_i$  demonstrated a measure of accuracy in its description of  
333 mountain pine beetle spread between 72% and 91%. Accuracy was highest in the initial  
334 years of the study when the mountain pine beetle infestation was relatively minimal,  
335 which is important as it is during this period that mitigation strategies could prove most  
336 effective at minimizing spread. Lower accuracy in later years of the study is likely a  
337 result of the limits of adequately predicting the transition from the Constant to Null  
338 classes.

339 The graphical comparison between the risk and severity classes is presented in  
340 Figure 6. The bars represent the severity classes for each year at time  $t$ , and the sections  
341 within the bars indicate the proportion of each risk class that corresponds with the  
342 specific severity class. One observation from the graphs is that the majority of locations  
343 that fall within the None severity class were also in the Null risk class. In addition, the  
344 Null risk class diminishes as severity increases. A proportion of the Light severity class  
345 was assigned to the Null risk class suggesting that the local Moran's  $I_i$  underestimates  
346 light infestations. Furthermore, there exists a small proportion of the None class that is  
347 composed of the Increase and Constant risk classes. This indicates that the local Moran's  
348  $I_i$  does not overestimate the severity of attack when no risk is present.

349

350 *Insert Figure 5 here*

351 *Insert Figure 6 here*

352

353 The Decline risk class only constitutes a very small proportion (i.e., 0% – 10%) of  
354 severity classes. However, the percentages increase in later years of the infestation  
355 indicating that certain locations experience declining populations over time. Furthermore,  
356 the highest percentage of the Decline class occurs in the Light severity class for 2005 and  
357 2006, which likely represents that these locations have been under attack for multiple  
358 years, but resources are now limited forcing populations to move to other areas.

359 The Increase and Constant risk classes both increase substantially as severity  
360 increases. Minimal proportions of these classes in the None severity class gradually  
361 increases in the Light severity class, and constitute the majority of the Moderate to Very  
362 Severe severity classes. Furthermore, during the earlier years of the infestation the  
363 Increase risk class is more prominent than the Constant class, the latter of which  
364 increases as the infestation grows. This indicates that, in general, there are more locations  
365 during the earlier part of the infestation that are being colonized by longer range dispersal  
366 (i.e., from outside a 1km x 1km cell) than short range. As the infestation grows, it is

367 likely that population levels increase to the point where forest stands with low  
368 susceptibility now become at risk to being attacked.

369

### 370 **3.3 Spatial Distribution of Risk Values**

371 The spatial distribution of risk classes for each year between 2002 and 2006 are  
372 presented in Figure 7. The maps illustrate the location over which beetle-induced pine  
373 mortality occurred over time and how the spatial distribution of risk classes changes from  
374 year to year. The result for 2002 depicts the Constant class in west-central British  
375 Columbia as well in dispersed satellite locations, all of which confer with observations of  
376 the current epidemic (Aukema et al. 2006). The Increase class generally surrounds the  
377 Constant class and is also located at distances from the core of the main infestation. Each  
378 year the Constant class grows outward from the initial nucleus, and the Increase class  
379 remains on the frontier of the infestation and in areas where mountain pine beetle likely  
380 engaged in longer-range dispersal. In general, most locations in the Increase class made  
381 the transition in later years to the Constant class as expected.

382

383 *Insert Figure 7 here*

384 The Decline class emerged in locations where the Constant class resided for  
385 several years. This is evident in the transition from the initial core of the infestation  
386 shown in red in 2002 that gradually makes the transition to the Decline class by 2006. In  
387 addition, there are several locations across the province – mainly in the locations distant  
388 from the core infestation – where class transition occurred from Increase to Decline. This  
389 is evident north of the main infestation from 2002 to 2003, the south-eastern edge of the  
390 main infestation between 2004 and 2005, and the scattered infestations along the southern  
391 border between 2005 and 2006. Many of these locations, especially in the south-eastern  
392 edge of the main infestation, eventually made the transition from the Decline to Constant  
393 class.

394

### 395 **4. Discussion**

396 In this study we aimed to investigate the utility of local indicators of spatial  
397 association, namely the bivariate local Moran's  $I_i$ , as a method for estimating risk of  
398 mountain pine beetle attack over very large areas with GIS and coarse-scale multi-  
399 temporal AOS data. Specifically, we were interested to determine if the bivariate local  
400 Moran's  $I_i$  could be used to define individual classes of risk that could overcome the  
401 limitations of using existing methods for the extent of the current epidemic. Rather than  
402 using a quantitative linear rating scale as per Bone et al. (2005), the local Moran's  $I_i$   
403 enables a definition of risk based on changes to beetle population levels. The qualitative  
404 risk indicators are useful for determining locations that are on the frontier of the  
405 infestations (i.e. the Increase class) versus locations where infestations are entrenched  
406 (i.e. the Constant class) versus those areas where populations are in decline. This  
407 information is used by forest managers to target different areas with specific mitigation  
408 strategies that account for local population dynamics.

409 While it is challenging to compare the accuracy of the presented approach with that of  
410 other risk rating systems, Zhu et al. (2008) developed regression models with similar  
411 explanatory power in a single year over a smaller spatial extent. However, the method  
412 presented in our study uses a strategic-level dataset and provides a level of accuracy that

413 would allow management to prioritize mitigation activities across large areas.  
414 Furthermore, not all Moran's  $I_i$  values were found to be significant, which means that  
415 efforts to utilize the bivariate local Moran's  $I_i$  for rating risk will have need to exercise  
416 caution in areas where spatial relationships are not entirely meaningful. However, it  
417 should be noted that in this study, the number of Moran's  $I_i$  values that were found to be  
418 significant coincided with the area impacted by mountain pine beetle (Figure 8). Thus, as  
419 the mountain pine beetle infested new areas, the bivariate local Moran's  $I_i$  captured the  
420 relationship between these locations and their surroundings.

421

422 *Insert Figure 8 here*

423

424 The nature in which locations change from one risk class to another did not always  
425 strictly adhere to the expectations outlined above, but nonetheless are indicative of  
426 previous observations of mountain pine beetle dynamics. For example, there exists  
427 several locations, most notably on the frontier of the infestations in early years, that make  
428 the transition straight from the Increase class to the Decline class without the population  
429 stabilizing for any period of time. This process, previously observed in some forest  
430 districts in British Columbia (Wulder et al. 2009), can be a result of either high insect  
431 mortality or an exhaustion of susceptible hosts. High mortality can be induced from  
432 extreme cold temperatures during the winter months (Safranyik 1989, Régnière and  
433 Bentz 2007), which will cause a sharp decline in populations that are on the rise.  
434 Alternatively, areas in the Decline class that had relatively high severity one year and a  
435 significant drop the next are likely a result of mountain pine beetle consuming available  
436 hosts and thus migrating to a new area in search of susceptible trees. Another observation  
437 regarding population dynamics is that numerous locations on the frontier of infestations  
438 made the transition from the Increase class to the Decline or Constant class and then back  
439 to the Increase class, indicating that populations can become dormant in localized frontier  
440 locations until enough insects from the core of the infestation reach these areas (et al.  
441 2006).

442 The risk rating classes derived from the bivariate local Moran's  $I_i$  are a sufficient  
443 step towards directing decision-makers on how to prioritize different areas given spread  
444 behavior. This is not to suggest that the Moran's  $I_i$  is a replacement for other risk rating  
445 approaches such as regression models (Robertson et al. 2008; Zhu et al. 2008) Instead  
446 there is a need to examine the integration of qualitative and quantitative rankings at  
447 appropriate scales. Over large geographic areas – such as the scale of the current outbreak  
448 – the bivariate local Moran's  $I_i$  provides a means to determine where more precise  
449 analyses can be carried out. In areas defined by the Increase Class, for example,  
450 regression models can be applied at finer scales to determine where to precisely focus  
451 mitigation efforts.

452

## 453 **5. Conclusion**

454 The potential for the mountain pine beetle to move further eastward into naïve forest  
455 environments and species (e.g., jack pine, *Pinus banksiana*) across the boreal forest of  
456 Canada (Safranyik et al. 2010) emphasizes the importance of developing methods to  
457 integrate broad scale datasets in a timely manner for efficiently devising mitigation  
458 strategies and assigning resources to areas of high priority. This is a common theme in

459 insect disturbance ecology as warming climates are leading to range expansions for a  
460 variety of insects, especially bark beetles in North America (Waring et al. 2009).

461 The GIS-based statistical method presented in this study builds on the previous  
462 research regarding risk ratings (Shore and Safranyik 1992), the use of local statistics for  
463 examining mountain pine beetle infestations (Long et al. 2010; Nelson and Boots 2008),  
464 and the use of multi-temporal spatial data for detecting changes in mountain pine beetle  
465 populations (Wulder et al. 2008). Moving forward, in order to make the local Moran's  $I_i$  -  
466 derived risk rating system operational, broad-scale susceptibility measures such as  
467 climatic variables and physiological stresses should be incorporated to help refine areas  
468 potentially subject to attack. This could involve future climate scenarios that can estimate  
469 the change in susceptible areas over time due to changes in temperature, precipitation,  
470 and other variables that have been found to influence beetle spread (Sambaraju et al.  
471 2011).

472

### 473 **ACKNOWLEDGEMENTS**

474

475 This project was funded by the Government of Canada through the Mountain Pine Beetle  
476 Program, a three-year, \$100 million Program administered by Natural Resources Canada,  
477 Canadian Forest Service (<http://mpb.cfs.nrcan.gc.ca/>). Part of this research was  
478 undertaken by Christopher Bone as a Post Doctoral Fellow, through the NSERC Visiting  
479 Fellowships program, at the Pacific Forestry Centre.

<b>Severity Class</b>	<b>Area Infested (%)</b>	<b>Area Infested in 2000 (ha)</b>	<b>Area Infested in 2006 (ha)</b>
Light	1-10	77, 746	2,933,172
Moderate	11-30	92, 554	2,933,172
Severe	31-49	114, 889	1,230,869
Very Severe	≥ 50	n/a	516,894

Table 1. Severity class as defined by the percentage of area infested by mountain pine beetle. Table also provides information on the total area infested in each class for the years 2000 (Westfall and Ebata 2001) and 2006 (Westfall and Ebata 2007). Note that the Very Severe and Trace classes were added in 2004. However, the Trace class is omitted here as no area in the study site was allocated to this class.
