ABSTRACT

Trials of a common set of seed lots representing 39 parents and five species of Alnus have been started in four countries: Belgium, Canada, the UK, and the US. Initial results indicate that cold hardiness is a problem in using A. acuminata but that sufficiently hardy A. rubra sources are available. A. glutinosa had the best growth in the nursery, and A. cordata had the best survival under severe moisture-stress conditions. A summary also is given of a workshop on alder improvement that further demonstrates the potential for developing the genus for biomass energy production.

Key words: Alnus acuminata, A. cordata, A. glutinosa, A. incana, A. rubra, seed source, cold hardiness, moisture stress tolerance.

INTRODUCTION

Depending on one's taxonomic viewpoint, the genus Alnus consists of $20 + {}^{1,2}$ or 35^3 species that are native to many parts of the northern hemisphere and to a limited area of Central and South America. The alders have been ranked behind such genera as Populus and Salix in their ability to produce rapid biomass growth in energy plantations. However, the ability of alders to symbiotically fix nitrogen at high rates in

"Included in evaluation trials,

soil has made them important trees for use in energy plantation systems in which frequent harvests will place a significant drain on site nutrient status. Hence, alders have been one of the genera focused on by the International Energy Agency (IEA) Forestry Energy Agreement. A directory of tree improvement programs in Alnus has been published,⁵ a breeding strategy was proposed for working with the genus, and an IEA joint evaluation trial including 30 entries of Alnus was established in 1985.7 As the IEA Agreement entered its second stage in 1986, the following problems/objectives were identified: (1) a limited number of Alnus species and provenances had been evaluated in international trials; (2) the availability of selected seed sources of *Alnus* and especially for hybrids within the genus was limited; and (3) there was a need for better exchange of information among groups that were working on Alnus to promote the advantages the genus offers and to solve the problems it presents. Therefore, the IEA sponsored 3 years of effort to address these three areas. This report will deal primarily with the early results related to the first objective. The results from objectives (2) and (3) will only be summarized, because a separate proceedings is being devoted to them based on a workshop held in August 1988.8

MATERIALS AND METHODS

Alder seed lots, seedling production, and test designs

A total of 39 seed lots representing five species was chosen as the most interesting of materials available for testing (Table 1). To the extent possible, three single parent tree seed lots were used for each of several regions within the range of a species that might be expected to perform well in participating countries. Unfortunately, it was not possible to represent A. incana as adequately as we would have liked because of the unavailability of seed from desired locations. The choice of A. cordata seed lots was based on the recommendations of Steenackers in Belgium and Teissier du Cros in France, who have some experience with the species. The choice of A. glutinosa seed lots was based on the results of provenance tests with the species in North America. It was known from a previous IEA test⁷ that only interior and very northern provenances of A. rubra would survive continental winters, so those were the sources emphasized in this study. One seed lot of A. acuminata was included because it is a promising species on the basis of its taxonomic relationship to the other species and its growth in its native habitat.1

The A. acuminata seed came from the seed supplies of R. B. Hall; all other seed lots were supplied from the IEA alder seed bank maintained by V. Steenackers in Belgium. Identical seed lots were distributed to all four participating countries: Belgium, Canada, the UK, and the US.

Seeds were sown in small containers (approximately 350 cm³ in soil volume) and grown under greenhouse conditions. In the Iowa trial, the seedlings were inoculated with a crushed nodule inoculum of local *Frankia* strains when they reached a stage at which they had several primary leaves. When the seedlings reached a height of approximately 15 cm, they were hardened off and then planted in nursery beds (Belgium, Canada, UK) or directly in a field site (US). The nursery planting design used three replications with six to eight trees per replication. The field planting design was a randomized block design with five replications and four-tree row-plots of each seed lot in each replication. Observations were then taken on bud set, survival, and height growth. Trees were judged to have completed bud set when the terminal bud showed no evidence of the production of new leaves and the bud felt hard when pressed between one's fingers.

To better incorporate this international joint evaluation trial with the testing of other *Alnus* germplasm in national programs, a system of interlocking blocks (Fig. 1) was followed in the field planting established in the US. This interlocking design allows for direct comparisons between the different entries in two different studies.

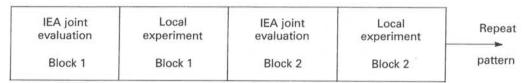

Fig. 1. An interlocking design for incorporating the IEA evaluation trial with national program trials of other *Alnus* germplasm sources.

Workshop

The *Alnus* tree improvement workshop was held on 8 and 9 August 1988. It began in Tacoma, Washington, USA, after a general IEA meeting. The first day was a field trip that included an inspection of an *A. rubra* provenance test at Puyallup, Washington, a tour of a very efficient red alder sawmill operated by Northwest Hardwoods (Arlington, WA), and travel across an elevation transect of the natural range of *A. rubra* along the Stillaguamish and Skagit Rivers in Washington. The second

day was devoted to the presentation and discussion of seven papers on various aspects of genetic variation and applied improvement efforts in *Alnus*. The paper session was hosted by Dr D. T. Lester and the Faculty of Forestry at the University of British Columbia, Vancouver, Canada.

RESULTS AND DISCUSSION

Seedling production

Several seed lots exhibited much lower than expected germination and this resulted in insufficient seedlings for testing of all seed lots at each location (Table 1). In addition, the *A. acuminata* seed lot did not prove cold hardy and was quickly lost from most of the trials. Although all cooperators started with the same seed lots, unanticipated problems were encountered in the germination and early growth of several seed lots. A 'No' in Table 1 indicates that insufficient seedlings were produced for field testing of that seed lot at that location. Field tests were established in all four countries in 1987 and 1988, but data are available for only two of the test sites at this time.

Fall dormancy in the United States

Table 2 gives the results of observations on bud set in all 39 seed lots at latitude 42°N at Ames, Iowa in the Fall of 1987. At that location, previous work has shown that the first week in October is a significant time for judging dormancy. 11 Killing frosts typically occur by 10 October. The percentage of seedlings that were dormant for each test entry ranged from 91% to zero. Only 20 of the 39 entries had 50% or more of their seedlings in a dormant condition. This is much less than expected from our previous field experiments in which a similar range of genetic materials had shown 80% of the first-year trees were dormant by 1 October. It seems that the onset of dormancy was delayed in these trees growing in containers in a hardening-off bed. Whether the relative rates and patterns of bud set between entries were the same as they would be under field conditions remains to be answered by correlation with a field test. Unexpectedly, one of the A. rubra entries from Idaho had the highest percentage of bud set. Indeed, all of the entries for A. rubra, except A.r. 48, set bud at a higher frequency than 50%. A general clinal trend of increasing bud set is shown in going from southern to northern entries of A. glutinosa. Entry A.g. 325 from Poland is a notable exception, displaying no bud set by 1 October. As a group, the A. incana

[&]quot;Percentage of trees with bud set on 1 October 1987.

entries were somewhat less advanced in developing dormancy than A. glutinosa and A. rubra. The A. cordata entries lagged still further behind in dormancy as might be expected because of the Mediterranean origin of the species. The A. acuminata entry showed no bud set and, indeed, was dead at the end of October when the containerized seedlings were moved to cold storage for the winter.

Nursery performance in Canada

Table 3 summarizes the survival and height growth measurements made over two seasons of growth in a nursery bed at Petawawa, Ontario. The 1988 growing season was particularly severe, exceptionally hot and dry. Due to those conditions, there was additional mortality of 39 trees and growth averaged only about 5 cm. Typical growth under field conditions can be expected to be at least 1.0 m.9 As a group, the *A. glutinosa* had relatively good survival and the best growth; *A. incana* had the best

survival and was second in growth; A. rubra still showed respectable survival (68.5%) after the second year. It is encouraging that these A. rubra entries seem to be much more winter hardy than the typical members of this species. The growth of A. rubra was relatively poor, however. The A. cordata entries in the test were also surviving as well as could be expected at the end of the second year, but their growth was the poorest of all the surviving species.

These early nursery results must be viewed with some caution. Our previous experience suggests that only a portion of the *A. rubra* and *A. cordata* entries will continue to be winter hardy when they grow above

the height of the protecting, winter snow cover. Furthermore, in a previous field study at Petawawa, A. incana outgrew A. glutinosa over the first 4 years. ¹² In longer-term field studies in the Netherlands, both A. cordata and A. incana entries were able to outgrow A. glutinosa. ¹³ The one A. acuminata entry in this test did not survive at all under the growing conditions in the nursery at Petawawa. The failure of this species in all the tests is not surprising because the species originates from the tropics. However, it might be worthwhile to do additional trials with A. acuminata sources from high elevations in the tropics. Growth and form of the species are very good under greenhouse conditions and it would be useful to find some trees of the species that could be used in interspecific breeding.

Field survival in the United States

After the study was field-planted in central Iowa, we experienced one of the worst growing-season droughts on record. Only 207 mm of rainfall was recorded at the planting site from the time of planting until the end of September 1988. Total precipitation for 1988 was 495 mm, compared with the long-term average of 816 mm for central Iowa. Consequently, extensive mortality occurred in the new plantation, as illustrated in Tables 4 and 5. To statistically analyze the mortality occurring in the four-tree plots of the field design, the data were transformed to account for the small sample size on each plot and the binomial nature of survival observations. Two of the blocks in the plantation showed nearly complete mortality — eight trees survived of 288 planted. Those two blocks were planted 1 week later than the others and were on a Vesser silt loam soil type, as compared with a Colo silty clay loam soil type. For the blocks with better survival.

Considered as groups by species, the *A. cordata* entries survived the best, and the *A. rubra* had the poorest survival under these strong moisture-stress conditions. The hot, dry Mediterranean climate where the *A. cordata* species originates probably has selected for trees that have more drought tolerance. The thick, shiny leaves of *A. cordata* are one observable trait that probably is a part of this drought tolerance. In contrast, the cool, moist climates where *A. rubra* originates would not have been likely to select for much drought tolerance in that species. One of the entries, *A.r.* 48, from the continental interior does show a reasonable level of survival that might be worthwhile under more normal growing conditions.

With the predictions of global warming trends, it may be very important to place a premium on selecting heat- and drought-tolerant plants for our energy plantations. Both A. cordata and A. glutinosa show

some promising entries in this regard. The variation in survival for A. glutinosa does not follow the geographic trend that one might expect. Several entries of northern European origin survived the best; some, but not all, southern sources showed the poorest survival. As an upland species, A. incana might also be expected to have good drought tolerance, but the limited number of entries of that species in this study averaged no better than A. glutinosa.

Summary of workshop papers8

L. Bouvarel and E. Tessier du Cros of the French INRA are testing 158 provenances of *A. glutinosa*, 7 *A. incana*, 45 *A. cordata*, 81 *A. rubra*, and 1 each of *A. hirusuta*, *A. inokumai*, and *A. rhombifolia*. Results to date include the following observations on growth:

TABLE 6

| | Dry weight yield | Height |
|--------------|------------------------------------------------|--------------------|
| A. glutinosa | 0·8-2·6 Mg ha ⁻¹ year ⁻¹ | 5-6·4 m at 6 years |
| A. cordata | 2-7 Mg ha ⁻¹ year ⁻¹ | 6-7.8 m at 6 years |
| A. rubra | 1-2·6 Mg ha ⁻¹ year ⁻¹ | 3-5 m at 4 years |

Some *A. rubra* have survived −20°C temperatures.

According to a provenance test conducted by A. Ager of the University of Washington, genetic variation in A. rubra is predictable by river drainage and elevation. Growth and dormancy patterns relate closely to heat sums and frost dates at origins, but 'cue' changes may be

large in moving trees long distances. Most of the variation in *A. rubra* is due to geographic origin with only small parent tree effects. The species has very little variation in specific gravity. Sources from poor sites with gravel soils allocate more growth to roots and nodules. However, the best means of selecting for improved nitrogen fixation rates is to select for aboveground biomass production. There is a close correlation between the results for *A. rubra* grown in Washington and France.

R. B. Hall reported that fast-growing, early-flowering hybrids of A. glutinosa have been produced through the F_2 generation. In addition, A. $incana \times glutinosa$ and A. $glutinosa \times rubra$ hybrids have been mass-produced in provenance test plantings. The A. $glutinosa \times rubra$ hybrids show hybrid vigor for growth under greenhouse conditions. These hybrids are also much easier to vegetatively propagate than A. glutinosa. In joint entomological studies with E. R. Hart (Iowa State University), Hall has found no satisfactory levels of resistance to the European alder leafminer, $Fenusa\ dohrnii$, in A. glutinosa. A. incana is moderately resistant. A. cordata and A. rubra are essentially immune to the insect. A. $glutinosa \times rubra$ hybrids show a range of resistance spanning the behavior of the two parental species.

R. N. Nyong'o (Iowa State University) has studied pollen dispersal in A. glutinosa and has found that the pollen travels farther than experience with other species would have suggested. At least a 400-m isolation strip is needed around seed orchards to exclude at least 91% of the alder

pollen from non-orchard sources.

CONCLUSION

The alder evaluation trials are just entering the establishment phase, but they do highlight some important points. We need to continue to improve the techniques for growing alder seedlings and getting good field establishment. The relatively poor tolerance of *Alnus* as a genus to moisture stress will be a limitation to its use in biomass plantations, but we probably can improve drought hardiness by working with species like *A. cordata*, by making selections within other species, and possibly through species hybridization. Improvement in biomass production will depend on similar procedures.

Three serious biological limitations in the present study need to be corrected in the future: (1) we need more A. incana germplasm from the central and southern portion of the species range to get a legitimate evaluation of its potential in biomass systems; (2) the value of hybrids needs much more study — none was available in sufficient quantity to

include in this joint evaluation at the time it started; and (3) we need to integrate the testing of alder species and hybrids with the evaluation of pure culture isolates of *Frankia* as they become available.^{12,16}
