ABSTRACT

This paper outlines the development and use of a compatible growth and yield model for red pine and white pine stands under a uniform shelterwood silvicultural system in the Algonquin Provincial Park. The model incorporates stand age, residual (postharvest) basal area, site index, composition index (proportion of pine basal area), and projected age as predictor variables for estimating residual gross merchantable pine volume and for projecting basal area and gross merchantable pine volume growth over a given time period. The results suggest that red pine and white pine stands in the park experience continually increasing volume growth for up to 25 years following uniform shelterwood harvesting over an age range of 40 to 130 years. The model is most suitable for making volume growth projections for periods of up to 25 years following uniform shelterwood harvesting.

RÉSUMÉ

Ce document décrit de façon succincte l'élaboration et l'utilisation d'un modèle compatible de la croissance et du rendement de peuplements de pins rouges et de pins blancs soumis à un régime sylvicole par coupes progressives uniformes dans le parc provincial Algonquin. Le modèle utilise l'âge du peuplement, la surface terrière résiduelle (postrécolte), l'indice de station, l'indice de composition (proportion de la surface terrière occupée par des pins) et l'âge projeté comme variables explicatives pour estimer le volume marchand brut résiduel de pin et prévoir la surface terrière et l'accroissement du volume marchand brut de pin pendant une période donnée. Les résultats permettent de supposer que les peuplements de pins rouges et de pins blancs du parc, lorsqu'ils sont âgés de 40 à 130 ans, connaissent un accroissement continu de leur volume au cours des 25 années postérieures à des coupes progressives uniformes. Le modèle est particulièrement bien adapté à l'établissement de prévisions de l'accroissement du volume pour des périodes allant jusqu'à 25 ans après la pratique de coupes progressives uniformes.

WHITE PINE AND RED PINE VOLUME GROWTH UNDER UNIFORM SHELTERWOOD MANAGEMENT IN ALGONQUIN PROVINCIAL PARK

INTRODUCTION

Estimating the growth and yield of forest stands that have been subjected to one or more selective harvests is an elusive task. This is particularly problematic in white pine (*Pinus strobus* L.) and red pine (*Pinus resinosa* Ait.) stands in the southern Great Lakes-St. Lawrence Forest Region, including the Algonquin Provincial Park, where the uniform shelterwood management system is applied. Yield tables and other management aids currently available for white pine and red pine have been based largely on old-growth, natural unmanaged stand data. These models do not provide reliable estimates of residual growth and yield beyond the initial harvest. Foresters must often adapt yield tables developed from unmanaged stands in order to predict the growth and yield of the managed forest (Tesch et al. 1983).

More reliable information on growth rates of pine in managed stands would aid in management planning and would assist forest managers in preparing preharvest silvicultural prescriptions. Information on the volume of red pine and white pine that could be expected in the future would aid forest industry clients in planning long-term capital improvements to their mills and harvest operations. The information could also help to determine long-term employment levels at the various mills that depend on pine from the park and adjacent areas.

The objective of this research is to develop volume growth models for white pine and red pine under uniform shelterwood management in the Algonquin Provincial Park.

METHODOLOGY

The Model

Predicting future yields following a selective harvest, such as might be carried out using a uniform shelterwood silvicultural system, requires detailed knowledge of the stand density (basal area) of pine and other tree species immediately following the harvest, some measure of site productivity (such as site index), and the age of the dominant and codominant pine trees in the residual stand. It also requires knowledge of the stand development process that occurs following release by harvesting.

The modeling approach used in this research was initially presented by Buckman (1962) and Clutter (1963). In his work with loblolly pine (*Pinus taeda* L.), Clutter (1963) developed a system of equations based on the concept that a derivative-integral relationship must exist between the

growth function and the yield function. In essence, a growth function, when integrated over time, should provide the same predicted value for yield as a yield function. Such a set of equations must constitute an algebraically consistent model for basal area and volume.

Development of the model was refined by Sullivan and Clutter (1972), who addressed the difficulties of correlated errors associated with repeated measurements on sample plots and the lack of statistical independence. Model development is based on simultaneously solving for three equations in one analysis for each species or species group, and requires two sets of measurements on each growth plot: one for residual (postharvest) conditions and another for present plot conditions. Thus:

$$[1] E(\ln V_1) = \beta_0 + \beta_1 S + \beta_2 A_1^{-1} + \beta_3 \ln B_1$$

$$[2] E(\ln V_2) = \beta_0 + \beta_1 S + \beta_2 A_2^{-1} + \beta_3 \ln B_2$$

$$[3] E(\ln B_2) = \left(\frac{A_1}{A_2}\right) \ln B_1 + \alpha_1 \left(1 - \frac{A_1}{A_2}\right) + \alpha_2 \left(1 - \frac{A_1}{A_2}\right) S$$

where E indicates expected value

$\ln V_i$ = logarithm to the base e of cubic-meter volume per hectare at the i^{th} measurement

S = site index in meters

A_i = stand age in years at the i^{th} measurement

$\ln B_i$ = logarithm to the base e of basal area per hectare in square meters at the i^{th} measurement

In most yield analyses employing least squares regression techniques, the logarithm of yield is often used as the dependent variable. This transformation is done in order to conform to the assumptions made in linear regression analysis, and as a means to mathematically express the interaction of independent variables with yield (Avery and Burkhart 1993). The measure of density is often subjected to logarithmic transformation, especially in models employing basal area (Avery and Burkhart 1993). Site index can sometimes be transformed using logarithmic or reciprocal transformation (Beck and Della-Bianca 1972), or it may not be transformed at all (Sullivan and Clutter 1972, Burkhart and Sprinz 1984). Stand age is often expressed as a reciprocal to allow for the "leveling off" (asymptotic) effect of yield with increasing age (Avery and Burkhart 1993).

The regression analysis involves developing a single model relating stand volume to initial stand age, projected age, site index, and initial basal area. This model is derived

by replacing $\ln B_2$ in Equation [2] with its expected value from Equation [3], to obtain:

$$[4] \quad E(\ln V_2) = \beta_0 + \beta_1 S + \beta_2 A_2^{-1} + \beta_3 \left(\frac{A_1}{A_2}\right) \ln B_1 \\ + \beta_4 \left(1 - \frac{A_1}{A_2}\right) + \beta_5 \left(1 - \frac{A_1}{A_2}\right) S$$

where $\beta_4 = \beta_3 \alpha_1$ and $\beta_5 = \beta_3 \alpha_2$

A more detailed description of the model formulation is given in Sullivan and Clutter (1972). Results from the regression analysis provide three equations: one for predicting volume per hectare immediately after harvest, another for predicting volume per hectare any time after the harvest, and a third that predicts the basal area at any time after the harvest.

This approach to growth and yield modeling has been successfully applied to a number of different species, including loblolly pine (Sullivan and Clutter 1972, Burkhart and Sprinz 1984), red pine (Buckman 1962), and yellow poplar (*Liriodendron tulipifera* L.) (Beck and Della-Bianca 1972). As presented by both Clutter (1963) and Sullivan and Clutter (1972), the desirable features of this yield model include the following:

- the mathematical form of the variates implies relationships that agree with our biological concepts of even-aged stand development;
- use of $\ln V$ as the dependent variable rather than V will generally be more compatible with the statistical assumptions customarily made in regression analysis (linearity, normality, additivity, and homogeneity of variance); and
- use of $\ln V$ as the dependent variate is a convenient way to mathematically express the interaction of the independent variables in their effect on V . (For example, the change in expected volume occurring as a result of a change in site index from 60 to 70 would depend on the associated values of $\ln B$ and A^{-1} .)

In the present study, one goal is to predict the yield of only a single species group—pine (i.e., white pine plus red pine), while still using stand characteristics such as total basal area per hectare, which describe a mixed stand composed of a number of species. Thus, the model must include a component that can describe the contribution of the single species group to the whole stand. One approach used to predict the yield for one species group growing in a mixed stand is the incorporation of a "composition index" into the yield model, as first applied by MacKinney and Chaiken (1939). This composition index (C) was measured as the ratio of basal area per hectare of the preferred species group to the total stand basal area, and was incorporated into the yield equation in the following way (MacKinney and Chaiken 1939):

$$[5] \quad E(\log Y) = \beta_0 + \beta_1 S + \beta_2 A^{-1} + \beta_3 \log SDI + \beta_4 C$$

Different transformations of the composition index were tested and a logarithmic transformation gave better estimations of pine yield. In addition, reciprocal transformation of site index also provided better empirical results in estimating yield.

Therefore, for this study, Clutter's (1963) model was modified to include a composition index in the form:

$$[6] \quad E(\ln V p_1) = \beta_0 + \beta_1 S^{-1} + \beta_2 \ln C + \beta_3 A_1^{-1} + \beta_4 \ln B_1$$

$$[7] \quad E(\ln V p_2) = \beta_0 + \beta_1 S^{-1} + \beta_2 \ln C + \beta_3 A_2^{-1} + \beta_4 \ln B_2$$

$$[8] \quad E(\ln B_2) = \left(\frac{A_1}{A_2}\right) \ln B_1 + \alpha_1 \left(1 - \frac{A_1}{A_2}\right) + \alpha_2 \left(1 - \frac{A_1}{A_2}\right) S^{-1} + \alpha_3 \left(1 - \frac{A_1}{A_2}\right) \ln C \\ + \alpha_4 (A_2 - A_1) + \alpha_5 (A_2 - A_1) S^{-1} + \alpha_6 (A_2 - A_1) \ln C$$

where $\ln V p_i$ = logarithm to the base e of gross merchantable volume (m^3) per hectare of pine at the i^{th} measurement

$\ln C$ = logarithm to the base e of composition index (basal area of pine divided by the total stand basal area per hectare at the $i=1$ measurement)

$\ln B_i$ = logarithm to the base e of total basal area (m^2) per hectare at the i^{th} measurement

All other variables are as described before.

The assumption was made that C remains constant over the projection period, which is valid for the short time periods for which the model is designed.

Note also that a variable describing the time since harvest (i.e., $[A_2 - A_1]$) was incorporated into Equation [8]. This term was included in the projected basal area model since there was significant empirical evidence that time since harvest, in addition to relative time since harvest (i.e., $[1 - A_1/A_2]$), contributed to the ability to predict future basal areas.

The regression analysis involves developing a single model relating stand volume to initial stand age, projected age, site index, initial total basal area, and initial composition index. This model is derived by replacing $\ln B_2$ in Equation [7] with their expected values from Equation [8], to obtain:

$$[9] \quad E(\ln V p_2) = \beta_0 + \beta_1 S^{-1} + \beta_2 \ln C + \beta_3 A_2^{-1} + \beta_4 \left(\frac{A_1}{A_2}\right) \ln B_1 \\ + \beta_5 \left(1 - \frac{A_1}{A_2}\right) + \beta_6 \left(1 - \frac{A_1}{A_2}\right) S^{-1} + \beta_7 \left(1 - \frac{A_1}{A_2}\right) \ln C \\ + \beta_8 (A_2 - A_1) + \beta_9 (A_2 - A_1) S^{-1} + \beta_{10} (A_2 - A_1) \ln C$$

Equation [9] produces a yield projection model that can estimate pine yield by using V_{p2} as the dependent variable. The model can also be adapted to estimate the yield of all species by using V_2 as the dependent variable. When $A_2 = A_1 = A$, i.e., the projection period is zero years, then $B_2 = B_1 = B$ and Equation [9] reduce to a general yield model:

$$[10] \ln Vp = \beta_0 + \beta_1 S^{-1} + \beta_2 \ln C + \beta_3 A^{-1} + \beta_4 \ln B$$

The projected basal area B_2 at the projected age A_2 in the form of Equation [8] can be solved from Equation [9] in the form:

$$[11] E(\ln B_2) = \left(\frac{A_1}{A_2} \right) \ln B_1 + \frac{\beta_5}{\beta_4} \left(1 - \frac{A_1}{A_2} \right) + \frac{\beta_6}{\beta_4} \left(1 - \frac{A_1}{A_2} \right) S^{-1} + \frac{\beta_7}{\beta_4} \left(1 - \frac{A_1}{A_2} \right) \ln C \\ + \frac{\beta_8}{\beta_4} (A_2 - A_1) + \frac{\beta_9}{\beta_4} (A_2 - A_1) S^{-1} + \frac{\beta_{10}}{\beta_4} (A_2 - A_1) \ln C$$

By taking the first derivative of the basal area yield model, Equation [11], with respect to age, the equation for instantaneous basal-area growth is (Beck and Della-Bianca 1972):

$$[12] \frac{dB}{dA} = B \cdot \left[A^{-1} \left(\frac{\beta_5}{\beta_4} + \frac{\beta_6}{\beta_4} S^{-1} + \frac{\beta_7}{\beta_4} \ln C \right) + \left(\frac{\beta_8}{\beta_4} + \frac{\beta_9}{\beta_4} S^{-1} + \frac{\beta_{10}}{\beta_4} \ln C \right) \right]$$

Similarly, the first derivative of the gross merchantable volume yield projection model, Equation [9], gives the volume growth model (Beck and DellaBianca 1972):

$$[13] \frac{dVp}{dA} = Vp \cdot \left[-\beta_2 A^{-2} + \beta_3 B^{-1} \frac{dB}{dA} \right]$$

The variable Vp^* is the gross merchantable yield predicted with Equation [10].

Data

The data was collected from 280 growth plots within the white pine working group and 42 growth plots from the red pine working group located on the eastern portion of the Algonquin Provincial Park. The plots were stratified according to site class and the number of years since harvesting had been carried out.

A minimum of two sets of measurements were derived from each growth plot for each working group; one describing the present condition of the plot, and another characterizing the residual (postharvest) condition. For those plots that were harvested more than 5 years ago, intermediate plot conditions at 5-year intervals starting at the time of harvest were also reconstructed.

Current breast height age of dominant/codominant pine trees within each plot was estimated by increment cores. Present stand age at breast height was estimated by taking the mean breast height age of residual pine stems. Age at the time of harvest was estimated by subtracting the years since harvest from the current age.

The diameter of all stumps found in the growth plots was also measured. The diameter at breast height (DBH) of these trees was estimated using stump diameter-DBH relationships developed by the Algonquin Forestry Authority.¹ This information was used to estimate the basal area of the stands prior to harvest. Accuracy of the stump diameter measurements was affected by the length of time since harvesting was carried out, since older stumps were often in advanced stages of decomposition.

All stems 9.0-cm DBH and over were measured and tallied to the nearest 0.1 cm. All white pine and red pine trees were increment cored at breast height. Bark thickness, and ring widths in 5-year intervals starting at the time of harvest, were measured to the nearest 1.0 mm. Past DBH's of white pine and red pine trees, in 5-year intervals starting at the time of harvest, were estimated based on current DBH, bark thickness, and increment data.

For all other species, individual trees showing no deformities were selected at random and increment cored at breast height. The total width of rings from the time of harvest to the present was measured to the nearest 1.0 mm. Past DBH's for these trees, in 5-year intervals starting at the time of harvest, were estimated by interpolation between current DBH and estimated DBH at the time of harvest. For all other trees, linear regression analysis was used to develop an empirical model for each species that would predict past DBH (DBH_t) as a function of current DBH (DBH_0) and elapsed time (t) from the present back to harvest, in the form:

$$[14] DBH_t = \beta_0 + \beta_1 DBH_0 + \beta_2 t + \beta_3 (DBH_0 \cdot t) + \beta_4 t^2 \\ + \beta_5 (DBH_0 \cdot t^2)$$

The results were used to estimate the past DBH of individual, noncored trees in 5-year intervals beginning at the time of harvest and extending to the present. For those species that did not have a sufficient number of samples to model past DBH growth, the equation developed for another species of the same family was used.

Total tree heights for all healthy, nondeformed white pine and red pine trees were measured to the nearest 0.1 m

¹ $DBH_{PW} = 2.19 + (0.819) \times (\text{stump diameter}); R^2 = 0.98$
 $DBH_{PR} = -0.756 + (0.912) \times (\text{stump diameter}); R^2 = 0.99$

using a suunto clinometer. For all other species, individual trees showing no deformities were selected at random for height measurements. Several different model forms for estimating height-diameter relationships, as given in Arabatzis and Burkhart (1992), were assessed. The polynomial form of the function:

$$[15] \quad H = \beta_0 + \beta_1 DBH + \beta_2 \sqrt{DBH} + \beta_3 DBH^2 + \beta_4 DBH^3$$

provided the best fit of the data for most species. For those species that did not have a sufficient number of samples to develop a height-diameter curve, the equation developed for another species of the same family was used. The results were used to estimate total height for trees not measured at present, and to estimate the heights of all trees at different time periods in the past. A correction factor was applied to past height estimates based on the ratio of measured current height to estimated current height.

Gross merchantable volume (GMV) of individual red pine and white pine trees was estimated using standard volume equations currently used by the Algonquin Forestry Authority. These use DBH and tree height as predictor variables. For all other species, merchantable volumes (stump height = 30 cm, minimum top diameter = 7 cm) were determined from existing equations (Honer et al. 1983).

Plot summaries of gross merchantable volume and basal area per hectare were compiled using standard mensurational techniques. If the past DBH of an individual tree was less than 9.0 cm, that tree was excluded from plot summary calculations for that measurement period only.

Site index for each plot was determined using site index curves developed for white pine within the Algonquin Provincial Park by the Ontario Ministry of Natural Resources. These curves require breast height age and total height as input variables. For those plots that did not have sufficient information (i.e., no white pine trees in the plot, no age estimate due to rotten increment cores, etc.), the age and/or average height of the plot was obtained from Forest Resource Inventory data for the stand. For plots in the red pine working group, site index at the age of 50 years was estimated from Plonski's yield tables (Plonski 1974).

All regression analyses were performed using the SASTM statistical computer package running on a SUN SPARC station. Least squares regression analysis was used for parameter estimation.

RESULTS

Table 1 lists statistics for individual trees tallied for the growth plot summary data by species. The parameter estimates for the individual tree, and diameter increment

Table 1. Summary statistics of individual tree characteristics tallied for the growth plot summaries by species.

equations developed for each species, are given in Table 2. Parameter estimates for the height-diameter curves developed for each species are given in Table 3. Table 4 provides summary statistics for the growth plots used in the analysis. Tables 5 and 6 show the distribution of plots by pine composition, site index, and number of measurements over time for the white pine and red pine working groups, respectively.

Figures 1 and 2 display time-series information on total basal area per ha and gross merchantable pine volume per ha, respectively, over plot age for each plot. Plots were separated into four site index classes to simplify presentation of the data.

The model as specified in Equation [9] was estimated using stepwise linear regression analysis, and by selecting only statistically significant ($p < 0.05$) variables. Results of this analysis indicated that the model fit the data very

well. (White pine working group, pine yield $R^2 = 0.97$, s.e. = 0.105; all species yield $R^2 = 0.94$, s.e. = 0.097. Red pine working group, pine yield $R^2 = 0.97$, s.e. = 0.083; all species yield $R^2 = 0.97$, s.e. = 0.07.) Not all independent variables in the yield model specified in Equation [9] were significant at the $p = 0.05$ level (Table 7). A plot of residuals against each independent variable showed no systematic distortions.

The results were used to develop growth and yield curves and yield tables for the white pine (Appendices 1 and 2) and red pine (Appendices 3 and 4) working groups, respectively. The site classes in the appendices correspond to Plonski's (1974) site classes for white pine and red pine. To convert site index to site class for white pine, site index values of 17.8 for Site Class 1, 12.1 for Site Class 2, and 9.0 for Site Class 3 were used. For the red pine working group, the three site classes had site index values of 18.6, 15.5, and 12.1, respectively.

All other variables as defined previously.

² n.s. = parameter estimate not significantly different from zero ($p = 0.05$).

*MSE = Mean square error.

**R² = Coefficient of determination.

Since gross merchantable volume was shown to vary with the proportion of pine in the residual stand, it was necessary to develop several growth and yield curves and yield tables that reflected the range of residual pine composition spanned by the data for each combination of working group and site class.

The basal area of the stands prior to harvest was estimated from information on stump diameters and residual basal area. This resulted in an estimation of the harvested basal area. Only stands harvested within the last 10 years were used to estimate this relationship. It was decided that diameter measurements taken on stumps from stands harvested more than 10 years ago might not be reliable and could introduce errors when estimating preharvest conditions. Appendix 5A depicts the relationship between the preharvest basal area and the basal area harvested of a particular species. The relationship between the percentage of basal area of red pine and white pine and the percentage

of total basal area occupied by those species is shown in Appendix 5B.

The instantaneous growth rate (immediately after harvest) and the periodic annual increment (P.A.I.) for the first 15 years after harvest were also estimated for the average stand on each site class. Figures 3.1a through 3.3b demonstrate how the instantaneous and periodic growth rates (volume and basal area) for pine will vary with the age of the residual pine at the time of harvest and the residual basal area. The most common conditions are represented by a stand having 70 percent residual pine based on basal area, an average age of residual pine of 90 years, and growing on Site Class 2.

DISCUSSION

The data used in the analysis represent stand conditions at various time periods since shelterwood harvesting was

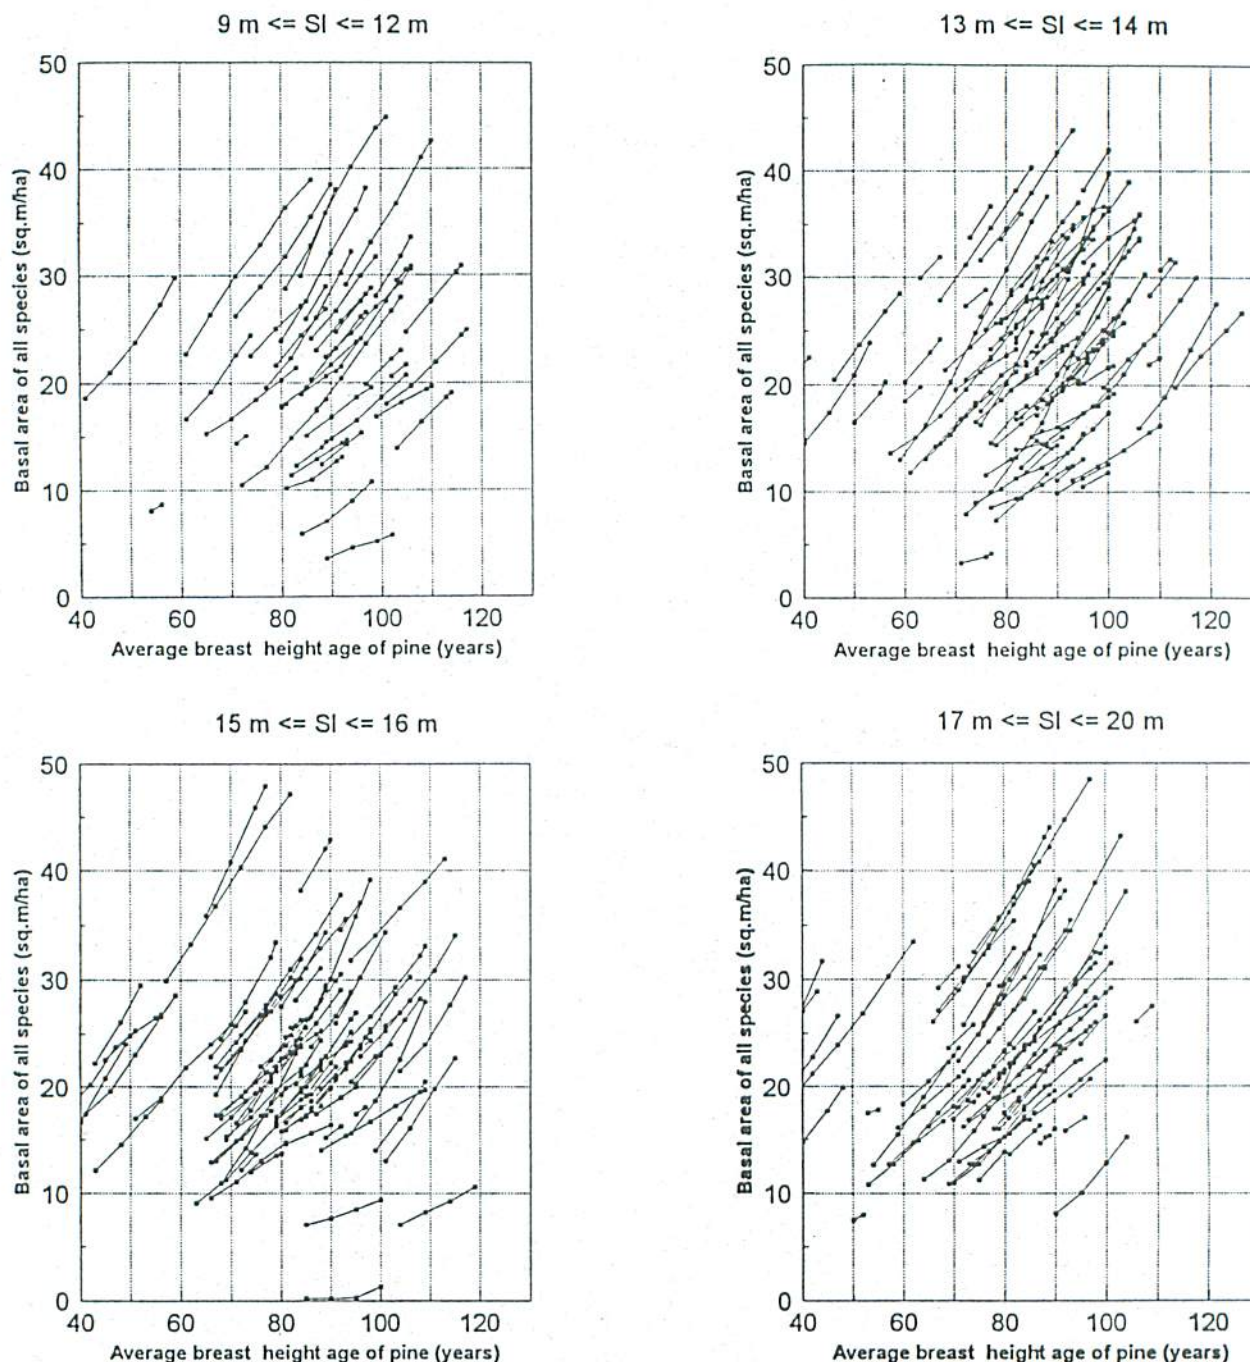

Figure 1. Basal area per hectare related to stand age and site index for growth plots.

last conducted. As no field measurements were carried out at the time of harvest, it was necessary to reconstruct the residual stand conditions that existed immediately after harvesting. Residual DBH's of most trees were calculated from current DBH and increment data. However, some trees were not increment cored. For these cases, data from cored trees were used with linear regression analysis to develop empirical models that would predict residual

DBH as a function of current DBH and elapsed time since harvesting (Equation [14]). Past DBH's estimated using this approach are considered to be extremely reliable. The R^2 was always greater than 0.89 and the maximum s.e. was 1.97 (Table 2).

The results of the height-diameter estimation for individual trees (Equation [15]) suggest that tree height can be reliably estimated as a function of DBH using polynomial

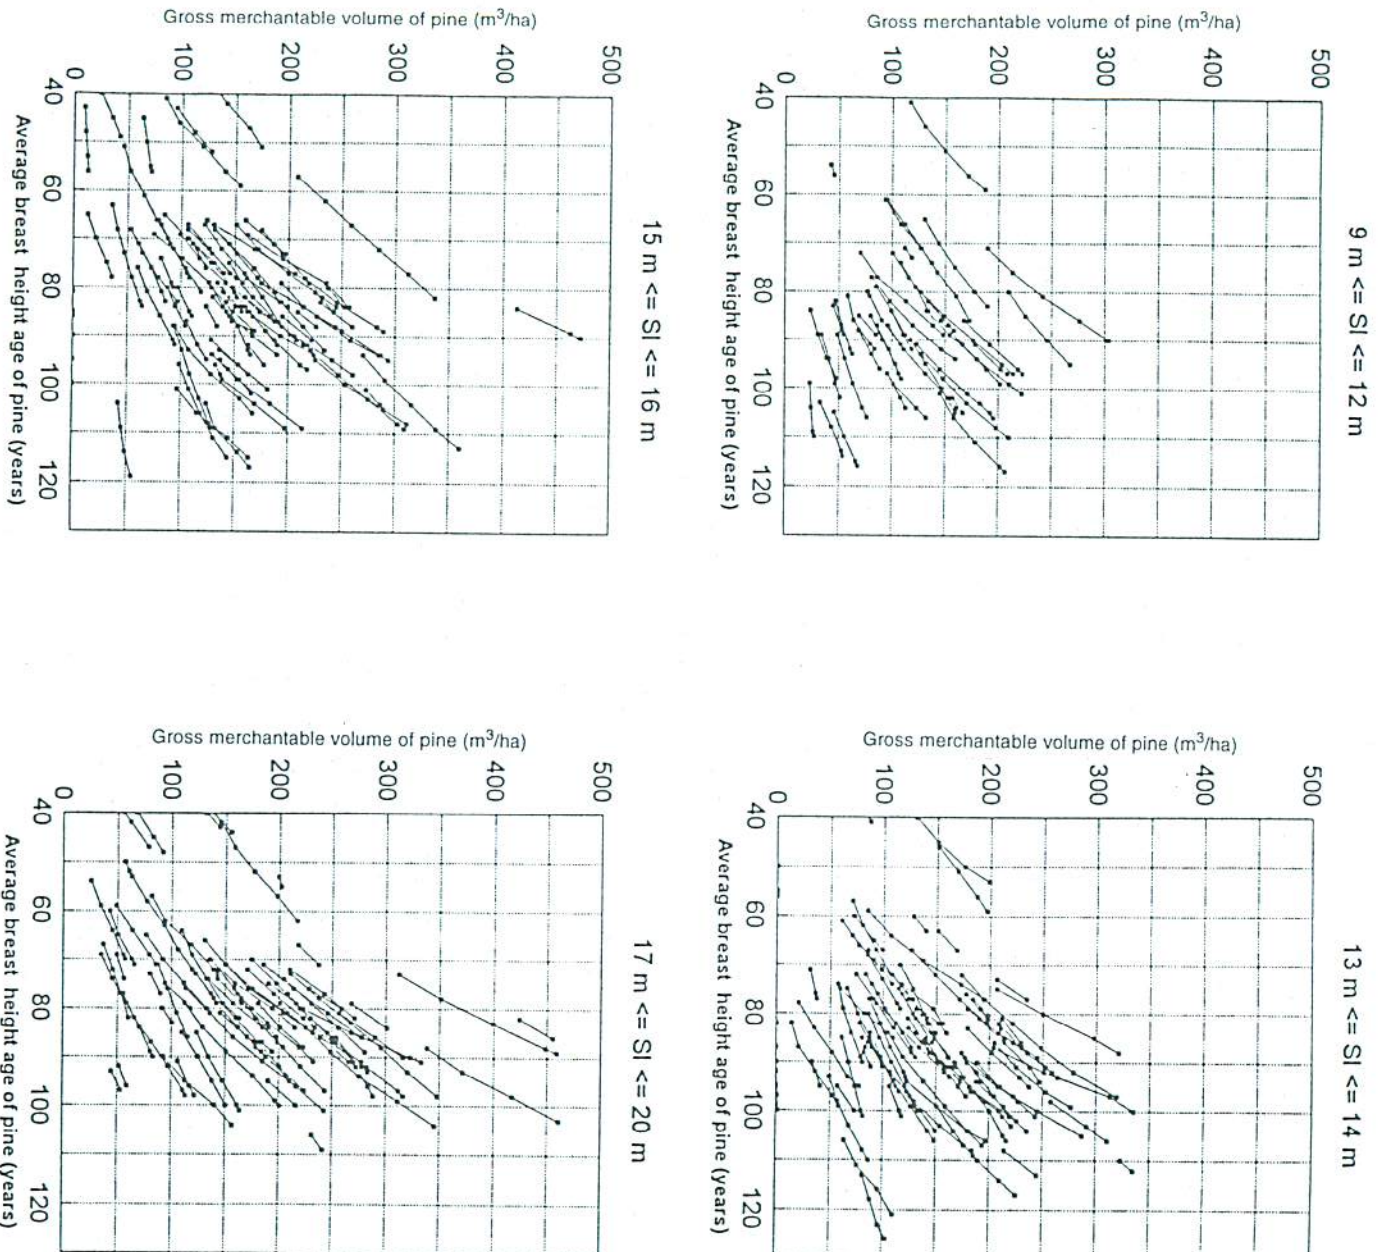

Figure 2. Gross merchantable volume per hectare related to stand age and site index for growth plots.

regression analysis. The R^2 varied from 0.38 to 0.76 depending on the species, and the s.e. varied from 1.51 to 3.09 (Table 3). Given the large number of observations taken for most species and the statistical significance of the height-diameter relationship, the height-diameter model represented by Equation [15] could be used to estimate individual tree height based on DBH for subsequent management decisions.

The data did not account for mortality that may have occurred since the stands were harvested, and no estimate of future mortality is included in the model. Therefore, the model will tend to underestimate the residual basal area and GMV immediately following the harvest, and may possibly overestimate future basal area and GMV. The effects of mortality on basal area and volume predictions are expected to be minor over short-term projections of

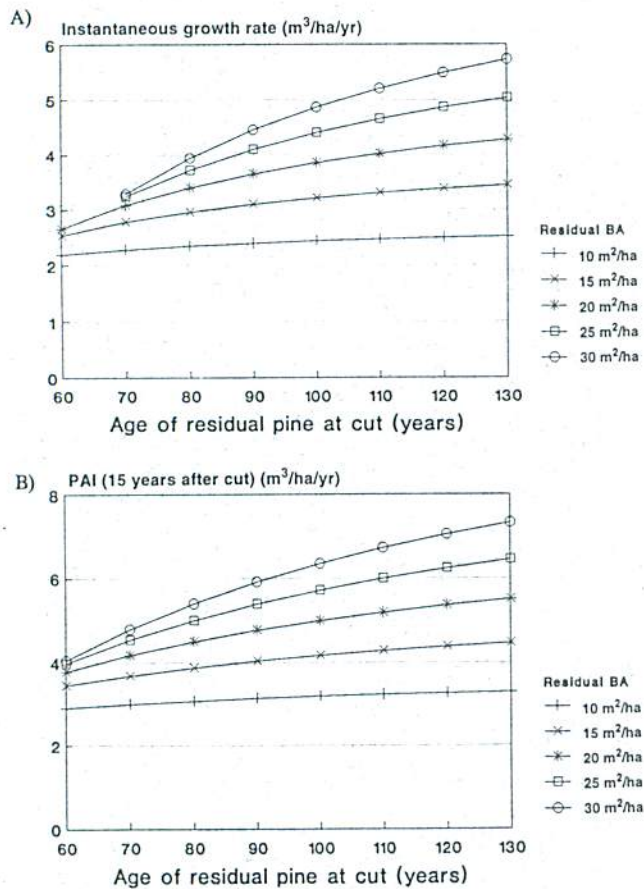

Figure 3.1. Growth rates of residual pines following a uniform shelterwood harvest growing on Site Class 1 (site index = 17.9 m) in the Algonquin Provincial Park. Graphs show the effects of average age of residual pine and the amount of residual basal area (m^2/ha) of all species on pine growth. (Projections were based on an average pine composition of 70 percent of the total basal area.) Growth rates are estimated both as (A) the instantaneous growth at harvest (i.e., first derivative of the yield equation) and (B) the projected periodic annual increment (P.A.I.) for the first 15 years after harvest.

5-year to 10-year growth periods, but could increase with longer growth periods. Therefore the model should not be used to project growth for more than 25 years after uniform shelterwood cutting, or in untreated stands. This problem could be overcome by using data from long-term permanent sample plots (Avery and Burkhart 1993).

The results of the volume growth models are consistent with those of Clutter (1963) and others. The results suggest that the total basal area growth and volume growth of white pine and red pine under uniform shelterwood man-

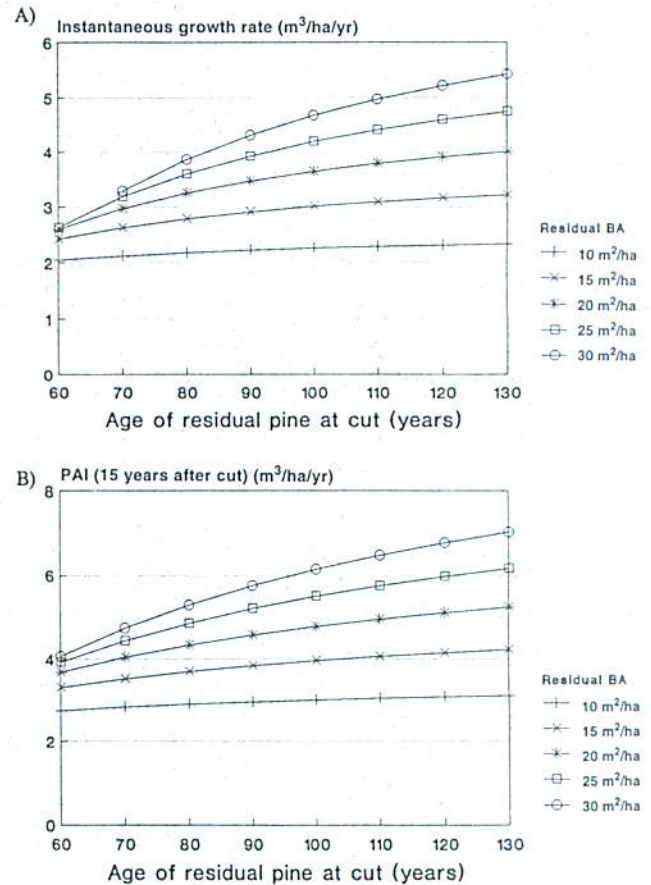

Figure 3.2. Growth rates of residual pines following a uniform shelterwood harvest growing on Site Class 2 (site index = 12.1 m) in the Algonquin Provincial Park. Graphs show the effects of average age of residual pine and the amount of residual basal area (m^2/ha) of all species on pine growth. (Projections were based on an average pine composition of 70 percent of the total basal area.) Growth rates are estimated both as (A) the instantaneous growth at harvest (i.e., first derivative of the yield equation) and (B) the projected periodic annual increment (P.A.I.) for the first 15 years after harvest.

agement are affected by site productivity as reflected in site index. Volume growth is also influenced by the proportion of pine in the residual stand.

With reference to Table 7 the positive sign on β_2 , the coefficient on the pine composition index, suggests that as the percentage of pine in the residual stand increases the GMV of pine in the stand also increases. This is consistent with intuitive expectations. However, the negative sign on the coefficient β_{10} indicates that as the percentage of pine in the residual stand increases, the overall basal area

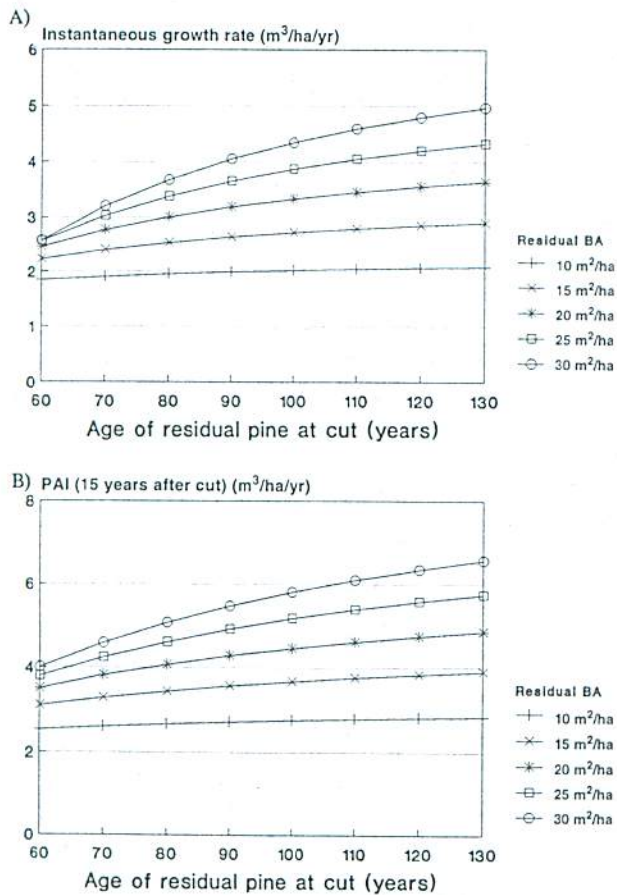

Figure 3.3. Growth rates of residual pines following a uniform shelterwood harvest growing on Site Class 2 (site index = 9.0 m) in the Algonquin Provincial Park. Graphs show the effects of average age of residual pine and the amount of residual basal area (m^2/ha) of all species on pine growth. (Projections were based on an average pine composition of 70 percent of the total basal area.) Growth rates are estimated both as (A) the instantaneous growth at harvest (i.e., first derivative of the yield equation) and (B) the projected periodic annual increment (P.A.I.) for the first 15 years after harvest.

growth of all species actually declines. One possible explanation for these two results is that pine may have slower basal area (diameter) growth, but faster volume (height) growth relative to other species.

The coefficient on β_2 is also positive and significant for the yield of all species for the white pine working group. This suggests that as the percentage of pine increases, the GMV for all species also increases. However, this does not hold true for the red pine working group, where the coefficient β_2 for all species is not significant. This could be due to low variability in pine composition for the red pine working

group plots, where more than 70 percent of the plots have 80–100 percent pine composition. In the white pine working group plots the pine composition exhibits greater variability (see Tables 5 and 6). The composition index does not affect the basal area growth of pine or of all species in the red pine working group.

Intuitively, volume yield per hectare would be expected to reach a maximum and then level off or decline after a certain age, depending on the species involved. For example, according to Plonski's (1974) normal yield tables for unmanaged white pine, Site Class 1, the species achieves its maximum yield after 190 years of age. This is well beyond the age of most of the stands used in the analysis. The sample plots used for the study do not show any growth decline over the periods measured. This growth habit is reflected in the model, where results suggest that the white pine and red pine stands in the Algonquin Provincial Park experience continually increasing volume growth for up to 25 years following uniform shelterwood harvesting over an age range of 40 to 130 years.

These results are also consistent with the field observations of forest managers who note that during the first 5 years following initial release through harvesting, energy expenditure in white pine and red pine is primarily for crown development. After 5 years following release, energy is used for stem development and volume growth.

The growth and yield models can be used to estimate the residual GMV of pine and all species in a stand at the time of harvest, and projected GMV over some management cycle (e.g., 15 to 20 years). Consider, for example, a stand within the white pine working group composed of 60 percent pine and growing on Site Class 2 as shown in Figure 4. Yield tables for the same stand are given in Table 8.

Assume that this stand has a breast height age for the residual pine of 90 years and has been thinned to a residual basal area of 23.9 m^2 per ha for all species. This stand closely resembles the "average" stand in the white pine working group.

To graphically project gross merchantable volume yield, it is necessary to first project basal area. On Figure 4a, locate point A (at age 90 and 23.9 m^2/ha). This point lies on the curve of expected development for a stand having a 4 m^2 per ha basal area at the age of 40. This implies that our example stand (age = 90, BA = 23.9) will develop in approximately the same way as a stand with a basal area of 4 m^2 per ha at the age of 40.

The residual GMV of pine is read off the left axis from Figure 4b. Enter at age 90 and go up to point B on the curve for a basal area of 4 m^2 per ha at the age of 40. Estimated pine GMV in the stand is approximately 135 m^3 per ha.

The residual GMV of all species is obtained from Figure 4c. Enter at age 90 and go up to point C on the curve for basal area of 4 m² per ha at the age of 40. Estimated GMV of all species in the stand is approximately 205 m³ per ha.

Assume a 15-year management cycle is anticipated. Projecting along the 4 m² per ha basal area at the age 40 curve

for 15 years (i.e., at age 105) in Figure 4a to point D reveals that the stand will have approximately a 35 m² per ha basal area for all species in 15 years time. Projecting along the 4 m² per ha basal area at the age 40 curve for 15 years in Figure 4b to point E the GMV of pine is estimated to be approximately 200 m³ per ha at the age of 105. Similarly, the GMV for all species is estimated to be 305 m³ per ha at the age of 105 (point F on Figure 4c).

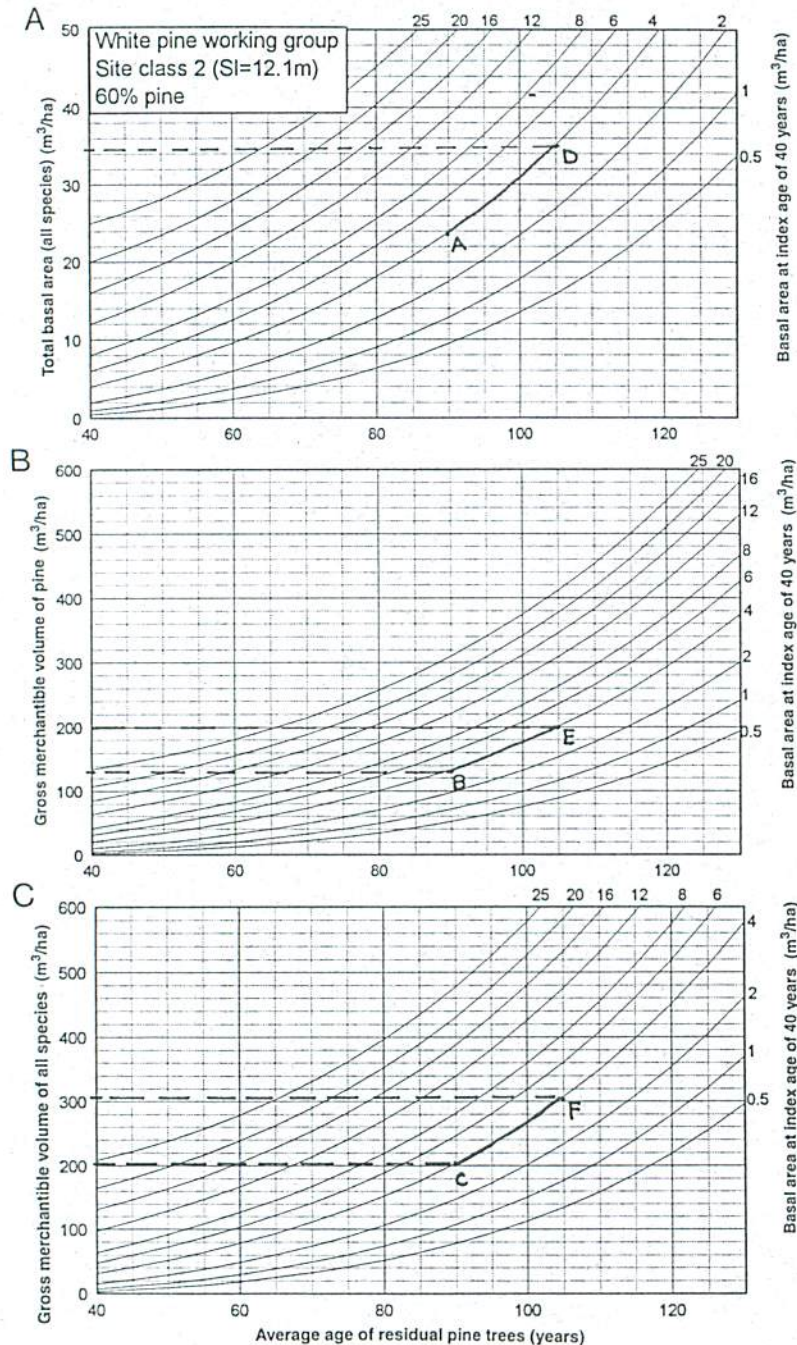

Figure 4. Application of the growth and yield model for an average stand within the white pine working group in the Algonquin Provincial Park, composed of 60 percent pine and growing on Site Class 2.

The GMV can also be read from the yield table (Table 8). Locate the residual stand age of 90 years in Table 8(a). Move across the row to a 23.9 m² per ha residual basal area for all species (highlighted with () brackets). This point falls within the column representing a residual basal area at the age of 40 of 4 m² per ha. The basal area for all species at the age of 105 is expected to be 35.2 m² per ha. In Table 8(b), locate the column representing a residual basal area at the age of 40 of 4 m² per ha and move down the column to the age of 90. The residual GMV of pine is 134.1 m³ per ha. The GMV of pine in the stand at the age of 105 is expected to be 201.0 m³ per ha. The residual GMV of all species is 204.5 m³ per ha and the GMV for all species at the age of 105 is expected to be 307.5 m³ per ha (Table 8c).

The model is estimated using data representing growth since the most recent harvest. As most of the plots are located in stands that have been harvested within the past 25 years, the volume projections are considered to be highly reliable over growth periods of up to 25 years. This is generally appropriate for purposes of management planning. However, there is considerable risk associated with using the results to project growth beyond 25 years, as might be desired when estimating the long-term timber supply.

With reference to Appendix 5A, the results indicate that the proportion of basal area of red pine and of all species harvested was relatively constant regardless of the preharvest basal area of those species. However, when the basal area of white pine in the stand was low (< 20 m² per ha), then 37 percent of the basal area of white pine was harvested on average; when the basal area of white pine was high, approximately 45 percent of the

white pine was harvested. This suggests that the silvicultural prescriptions favored leaving white pine in stands where the preharvest basal area of that species was low, and increased the proportion of white pine harvested when it was more prevalent in the stand. These conclusions are supported by Appendix 5B.

The instantaneous volume growth rate and periodic annual volume increment for the first 15 years after harvest are observed to vary according to site class, although conditions of 70 percent residual pine by basal area and an average age of residual pine of 90 years are held constant over all three site classes (Table 9a). Pine volume growth represents 70 to 90 percent of the total volume growth depending on the site class.

When referring to Table 9b, the reader will note that the basal area growth rate for other species is shown as zero, although volume growth attributed to other species is indicated in Table 9a. This is not to suggest that the basal area of other species did not increase following harvest. However, the data reveal that pine represents the larger diameter and dominant stems in the residual stands while other species tend to be suppressed with correspondingly smaller diameter stems. Thus pine will tend to dominate total basal area growth following harvest.

CONCLUSIONS

A model has been developed to estimate growth and yield in red pine and white pine stands under uniform shelterwood management in the Algonquin Provincial Park. The total basal area growth and volume growth of these trees under uniform shelterwood management are affected by site productivity and the proportion of pine in the residual stand. The results also suggest that red pine and white pine stands in the park experience continually increasing volume growth following uniform shelterwood harvesting over an age range of 40 to 130 years.

The model can be used to make volume growth projections over periods of up to 25 years. This is generally appropriate for purposes of management planning and for preparing preharvest silvicultural prescriptions for stands in red pine and white pine working groups. However, there is considerable risk associated with using the results to project growth beyond 25 years, as might be desired when estimating the long-term timber supply.

It should be noted that these models have been developed from Algonquin Provincial Park data and must be tested and calibrated for other sites.

Table 9. Instantaneous and periodic growth in (A) gross merchantable volume and (B) basal area of the "average" white pine stand managed under the uniform shelterwood system in the Algonquin Provincial Park.

Characteristics of this "average" white pine stand include:

- 70 percent pine after cut ($Pw_6 Pr_1 OH_3$)
- average age of residual pine is 90 years
- residual basal area of all species is 20 m²/ha

A) Gross merchantable volume						
Site Class	Instantaneous growth (m ³ /ha per yr)			P.A.I. (for 15 years after cut) (m ³ /ha per yr)
